Review/Questions Lambda

Functional Programming Object Oriented Programming Python Classe Subclassing/Inheritance

Homework review

Homework Questions?

lambda

"Anonymous" functions

```
In [171]: f = lambda x, y: x+y
```

In [172]: f(2,3)

Out[172]: 5

Can only be an expression – not a statement

lambda

Called "Anonymous": it doesn't need a name. It's a python object, it can be stored in a list or other container

```
In [7]: 1 = [lambda x, y: x+y]
In [8]: type(1[0])
Out[8]: function
```

And you can call it:

```
In [9]: 1[0](3,4)
Out[9]: 7
```

functions as first class objects

You can do that with "regular" functions too:

```
In [12]: def fun(x,y):
   . . . . :
         return x+y
   . . . . :
In [13]: 1 = [fun]
In [14]: type(1[0])
Out[14]: function
In [15]: 1[0](3,4)
Out[15]: 7
```

map

map "maps" a function onto a sequence of objects — It applies the function to each item in the list, returning another list

Out[25]: [14, 20, 24, 34, 22, 18]

But if you only need that function once:

```
In [26]: map(lambda x: x*2 + 10, 1)
Out[26]: [14, 20, 24, 34, 22, 18]
```

filter

filter "filters" a sequence of objects with a boolean function — It keeps only those for which the function is True

To get only the even numbers

In
$$[27]$$
: 1 = $[2, 5, 7, 12, 6, 4]$

reduce

reduce "reduces" a sequence of objects to a single object with a function that combines two arguments To get the sum:

```
In [30]: 1 = [2, 5, 7, 12, 6, 4]
In [31]: reduce(lambda x,y: x+y, 1)
Out[31]: 36
```

To get the product:

```
In [32]: reduce(lambda x,y: x*y, 1)
```

Out[32]: 20160

comprehensions

Couldn't you do all this with comprehensions?

Yes:

```
In [33]: [x+2 + 10 for x in 1]
Out[33]: [14, 17, 19, 24, 18, 16]
```

```
In [34]: [x for x in 1 if not x%2]
```

Out[34]: [2, 12, 6, 4]

Except Reduce

But Guido thinks almost all uses of reduce are really sum()

functional programming

Comprehensions and map, filter, reduce are all "functional programming" approaches

map, filter and reduce pre-date comprehensions
in Python's history

Some people like that syntax better

And "map-reduce" is a big concept these days for parallel processing of "Big Data" in NoSQL databases.

(Hadoop, MongoDB, etc.)

lambda

Can also use keyword arguments

Note when the keyword argument is evaluated: this turns out to be handy

LAB

- Write a function that returns a list of n functions, such that each one, when called, will return the input value, incremented by an increasing number.
- Use a for loop, lambda, and a keyword argument

```
code/lambda/lambda_keyword.html(rst)
code/lambda/lambda_keyword.py
code/lambda/test_lambda_keyword.py
```

More about Python implementation than OO design/strengths/weaknesses

One reason for this: Folks can't even agree on what OO "really" means

The Quarks of Object-Oriented Development - Deborah J. Armstrong:

http://agp.hx0.ru/oop/quarks.pdf

Is Python a "True" Object-Oriented Language?

(Doesn't support full encapsulation, doesn't require objects, etc...)

I don't Care!

Good software design is about code re-use, clean separation of concerns, refactorability, testability, etc...

OO can help with all that, but:

- It doesn't guarantee it
- It can get in the way

Python is a Dynamic Language

That clashes with "pure" OO

Think in terms of what makes sense for your project – not any one paradigm of software design.

00 for this class:

"Objects can be thought of as wrapping their data within a set of functions designed to ensure that the data are used appropriately, and to assist in that use"

http://en.wikipedia.org/wiki/Object-oriented_programming

Even simpler:

Objects are data and the functions that act on them in one place.

In Python: just another namespace.

The OO buzzwords:

- data abstraction
- encapsulation
- modularity
- polymorphism
- inheritance

You can do OO in C (see the GTK+ project)

"OO languages" give you some handy tools to make it easier (and safer):

- polymorphism (duck typing gives you this anyway)
- inheritance

OO is the dominant model for the past couple decades

You will need to use it:

- It's a good idea for a lot of problems
- You'll need to work with OO packages

Some definitions

```
class A category of objects: particular data and behavior: A "circle" (same as a type in python)
```

instance A particular object of a class: a specific circle

object The general case of a instance – really any value (in Python anyway)

attribute Something that belongs to an object (or class) – generally thought of as a variable, or single object, as opposed to a ...

method A function that belongs to a class

The class statement

class creates a new type object:

```
In [4]: class C(object):
    pass
    ...:
In [5]: type(C)
Out[5]: type
```

It is created when the statement is run - much like def

```
(note on "new style" classes)
```

Note about the book (TP):

Chapters 15 and 16 use a style that generally isn't recommended:

```
In [6]: class Point(object):
    ...:    pass
In [7]: p = Point()
In [8]: p.x = 4
In [9]: p.y = 2
```

Python is Dynamic – you can do this, but you generally want more structure, defaults, etc.

About the simplest class:

```
>>> class Point(object):
   x = 1
       v = 2
>>> Point
<class __main__.Point at 0x2bf928>
>>> Point.x
>>> p = Point()
>>> p
<__main__.Point instance at 0x2de918>
>>> p.x
```

Basic Structure of a real class:

```
class Point(object):
# everything defined in here is in the class namespace
    def __init__(self, x, y):
        self.x = x
        self.y = y
## create an instance of that class
p = Point(3,4)
## access the attributes
print "p.x is:", p.x
print "p.y is:", p.y
see: code/simple_class
```

The Initializer

The __init__ special method is called when a new instance of a class is created.

You can use it to do any set-up you need

```
class Point(object):
    def __init__(self, x, y):
        self.x = x
    self.y = y
```

It gets the arguments passed to the class constructor

self

The instance of the class is passed as the first parameter for every method.

"self" is only a convention — but you DO want to use it.

```
class Point(object):
    def a_function(self, x, y):
...
```

Does this look familiar from C-style procedural programming?

```
class Point(object):
    def __init__(self, x, y):
        self.x = x
    self.y = y
```

Anything assigned to a self. attribute is kept in the instance name space

That's where all the instance-specific data is.

```
class Point(object):
    size = 4
    color= "red"
    def __init__(self, x, y):
        self.x = x
        self.y = y
```

Anything assigned in the class scope is a class attribute – every instance of the class shares the same one.

```
class Point(object):
    size = 4
    color= "red"
...
    def get_color():
        return self.color
>>> p3.get_color()
    'red'
```

class attributes are accessed with self also..

Typical methods

```
class Circle(object):
    color = "red"
    def __init__(self, diameter):
        self.diameter = diameter

def grow(self, factor=2):
    self.diameter = self.diameter * factor
```

methods take some parameters, manipulate the attributes in self

Python Classes

Gotcha!

```
def grow(self, factor=2):
        self.diameter = self.diameter * factor
In [205]: C = Circle(5)
In [206]: C.grow(2,3)
TypeError: grow() takes at most 2 arguments (3 given)
Huh???? I only gave 2
("self" is implicitly passed in...)
```

Let's say you need to render some html...

The goal is to build a set of classes that render an html page: sample_html.html

We'll start with a single class, then add some sub-classes to specialize the behavior

More details in week-06/LAB_instuctions.rst(html)

Step 1:

- Create an "Element" class for rendering an html element (xml element).
- It should have class attributes for the tag name and the indentation
- the constructor signature should look like:
 Element(content=None) where content is a string
- It should have an "append" method that can add another string to the content
- It should have a render(file_out, ind = "") method that renders the tag and the strings in the content. file_out could be any file-like object. ind is a string with enough spaces to indent properly.

Inheritance

In object-oriented programming (OOP), inheritance is a way to reuse code of existing objects, or to establish a subtype from an existing object.

. . .

objects are defined by classes, classes can inherit attributes and behavior from pre-existing classes called base classes, or super classes.

The resulting classes are known as derived classes or subclasses.

```
(http://en.wikipedia.org/wiki/Inheritance_%28object-oriented_programming%29)
```

Subclassing

A subclass "inherits" all the attributes (methods, etc) of the parent class.

You can then change ("override") some or all of the attributes to change the behavior.

The simplest subclass in Python:

```
class A_Subclass(The_SuperClass):
    pass
```

A_subclass now has exactly the same behavior as The_SuperClass

Overriding attributes

Overriding is as simple as creating a new attribute with the same name:

```
class Circle(object):
    color = "red"
...
class NewCircle(Circle):
    color = "blue"
>>> nc = NewCircle
>>> print nc.color
blue
```

all the self instances will have the new attribute

Overriding methods

Same thing, but with methods

```
class Circle(object):
. . .
    def grow(self, factor=2):
        """grows the circle's diameter by factor"""
        self.diameter = self.diameter * factor
. . .
class NewCircle(Circle):
. . .
    def grow(self, factor=2):
        """grows the area by factor..."""
        self.diameter = self.diameter * math.sqrt(2)
```

all the instances will have the new method

Review/Questions Lambda Functional Programming Object Oriented Programming Python Classes Subclassing/Inheritance

"Here's a program design suggestion: whenever you override a method, the interface of the new method should be the same as the old. It should take the same parameters, return the same type, and obey the same preconditions and postconditions. If you obey this rule, you will find that any function designed to work with an instance of a superclass, like a Deck, will also work with instances of subclasses like a Hand or PokerHand. If you violate this rule, your code will collapse like (sorry) a house of cards."

ThinkPython 18.10

Step 2:

- Create a couple subclasses of Element, for a <body> tag and
 tag. Simply override the tag class attribute.
- Extend the Element.render() method so that it can render other elements inside the tag in addition to strings. Simple recursion should do it. i.e. it can call the render() method of the elements it contains.
- Deal with the content items that could be either simple strings or Elements with render methods...there are a few ways to handle that...

Step 3:

- Create a <head> element simple subclass.
- Create a OneLineTag subclass of Element: It should override the render method, to render everything on one line – for the simple tags, like:
 - <title> PythonClass Class 6 example </title>
- Create a Title subclass of OneLineTag class for the title.
- You should now be able to render an html doc with a head element, with a title element in that, and a body element with some <P> elements and some text.

Homework

Catch Up!

Read up on OO if you haven't already

Finish today's Lab

Finish other Homework / Labs you may not have gotten to.
